RESEARCH MEMORANDUM

EFFECT OF FUEL INJECTORS AND LINER DESIGN ON PERFORMANCE OF

AN ANNULAR TURBOJET COMBUSTOR WITH VAPOR FUEL.

By Carl T. Norgren and J. Howard Childs

SUMMARY

A direct-connect duct investigation was conducted with a one-quarter segment of a $25\frac{1}{2}$ -inch-diameter annular combustor which had been previously developed for liquid fuel injection. This combustor was modified by changing the fuel injectors and the liner design for vapor fuel injection. A total of 11 fuel injection schemes and 2 liner airentry hole patterns were investigated as well as a liner designed for low pressure drop. Values quoted subsequently for simulated flight performance refer to operation of the combustor in a typical 5.2 pressure ratio turbojet at a flight Mach number of 0.6.

The combustor giving highest combustion efficiencies (model 14I) produced efficiencies above 98 percent at altitudes up to 61,000 feet at cruise (85 percent rated) engine speed. Increasing the air flow rate through this combustor to a value 69 percent above current design practice resulted in no appreciable effect on combustion efficiency at 56,000 feet at cruise speed. However, the outlet temperature profile for this combustor was unsatisfactory, and the pressure drop through the combustor was approximately twice as great as for many production-model combustors.

The combustor designed for low pressure drop (model 151) gave a pressure drop only 60 percent of that for model 141, but the combustion efficiency of this combustor was low. The data indicate that combustion efficiency could be improved by a liner design change to increase the amount of air entering the primary combustion zone.

INTRODUCTION

A general research program is in progress at the NACA Lewis laboratory to determine design criteria for turbojet combustors. One objective of this general program is the development of combustors that operate efficiently at lower pressures and at higher air flow rates, as

pointed out in reference 1. The experimental combustor described in reference 1 operated with a higher combustion efficiency at severe conditions when using vapor fuel than when using liquid fuel despite the fact that the combustor was originally developed to obtain high performance with liquid fuel. No attempt was made in reference 1 to optimize the combustor design for handling vapor fuel.

The research reported herein is a continuation of the work of reference 1. The first objective of the research was to improve the combustor of reference 1 to obtain higher combustion efficiencies with vapor fuel. The second objective was to reduce the combustor pressure loss, since the total-pressure loss through the combustor of reference 1 was approximately twice as high as the pressure losses obtained with several production model combustors.

A direct-connect duct investigation was conducted with a one-quarter segment of a $25\frac{1}{2}$ -inch-diameter annular turbojet combustor using vapor fuel. The data obtained with vapor fuel are believed to be representative of the performance to be expected when a fuel vaporizer is incorporated into the combustor. The initial combustor configuration was identical with the combustor of reference 1. The fuel injectors and the air-entry holes in the combustor liner were altered so that the combustor was better adapted for operation with vapor fuel. A total of 11 fuel injection schemes and 2 air-entry hole patterns were investigated. A new combustor liner designed for low pressure drop was also included in this investigation.

The operating conditions investigated included low pressure conditions typical of high-altitude, reduced-throttle flight and air flow rates per unit combustor frontal area which are typical of current engine design practice and 69 percent above current practice. The data presented include combustion efficiencies, pressure losses, and combustor-outlet temperature profiles over a range of fuel-air ratios. The performance data are compared with similar data for the combustor of reference 1.

APPARATUS

Installation and Instrumentation

The combustor installation and instrumentation were identical with those of reference 1. A diagram of the combustor installation is shown in figure 1. The combustor-inlet and combustor-outlet ducts were connected to the laboratory air supply and low-pressure exhaust systems, respectively. Air flow rates and combustor pressures were regulated by remote-controlled valves located upstream and downstream of the combustor. The combustor inlet-air temperature was controlled by an electric heater.

NACA RM E53BO4

Air flow was metered by a concentric-hole, sharp-edge orifice installed according to A.S.M.E. specifications. The vapor fuel flow rate was metered by a calibrated sharp-edge orifice. Thermocouples and pressure tubes were located at the combustor-inlet and -outlet planes indicated in figure 1. The number, type, and position of these instruments at each of the planes are indicated in figure 2. The combustor-outlet thermocouples were located at centers of equal areas in the duct. Pressure tubes were connected to absolute manometers; thermocouples, to a recording potentiometer.

The fuel used in this investigation was vaporized commercial propane from the laboratory distribution system.

Combustors

Each combustor was designed to fit into the same combustor housing, which consisted of a 1/4 segment of a single-annulus combustor having an outside diameter of $25\frac{1}{2}$ inches, an inside diameter of $10\frac{5}{8}$ inches, and a length from fuel atomizers to combustor-outlet thermocouples of approximately 23 inches. The maximum combustor cross-sectional area was 105 square inches (corresponding to 420 sq in. for the complete combustor).

A total of three combustor liners was investigated. The first of these liners, model 13, was identical with the combustor of reference 1. A cutaway view of the model 13 liner installed in the combustor housing is presented in figure 3; figure 4 shows a longitudinal cross-sectional view of this liner; and figure 5 shows the arrangement of the air-entry holes in the liner.

The model 14 liner resulted from design modifications to better adapt the combustor for handling vapor fuel. This liner (fig. 6) differed from the model 13 liner in two important respects: (1) the airentry holes at the upstream end of the liner were larger; and (2) the radiation shield, which protects the fuel injectors from flame radiation, was perforated to admit air into the combustion zone in an axial direction.

The details of the model 15 liner, which was designed to give low pressure drop, are presented in figure 7. The walls of the liner did not diverge as did those of models 14 and 15. The air-entry holes in the walls of the model 15 liner were identical with those in model 13.

The fuel injectors were located in a manifold at the upstream end of the combustor and injected fuel in the downstream direction. Some of the combustors reported herein utilized 10 fuel injectors, while others

utilized only 5 fuel injectors. To permit operation with either 5 or 10 fuel injectors, a dual manifold (shown in fig. 8) was used. The various fuel injectors which were used in this investigation are shown in figure 9. These fuel injectors were designed to produce various fuel distribution patterns.

A total of 11 fuel injector configurations and 3 combustor liner configurations was investigated; these are tabulated and described in table I. Each combustor is given a numerical designation to indicate the liner configuration (13, 14, or 15) followed by a letter designation to indicate the fuel injector design.

PROCEDURE

Combustion efficiency and combustor total-pressure loss data were recorded for a range of fuel-air ratios at the following conditions:

	Combustor inlet total pressure, P _i , in. Hg abs		Air flow rate per unit area, Wa/Ar, lb/(sec)(sq ft)	Simulated flight altitude in reference engine, cruise speed
A	15	268	2.14	56,000
B	8	268	1.14	70,000
C	5	268	.714	80,000
E	15	268	3.62	56,000

These conditions simulate operation of the combustor in a reference turbojet engine which is a typical 5.2 pressure ratio turbojet operating at a Mach number of 0.6. The cruise speed of the engine is assumed to be 85 percent of the rated rotor speed. Test conditions A through C require air flow rates per unit combustor frontal area which are typical of current turbojet engines. Test condition E requires an air flow rate which is 69 percent above current practice.

Combustion efficiency was computed as the percentage ratio of actual to theoretical increase in enthalpy from the combustor-inlet to the combustor-outlet instrumentation planes using the method of reference 2. For calculation of combustor-outlet enthalpy, the temperature was computed as the arithmetic mean of the 30 outlet thermocouple indications for most of the data presented herein. For a limited number of data points the average combustor-outlet temperature was computed from the relation

$$T_{av} = \frac{\sum_{n=1}^{n=30} m_n T_n}{\sum_{n=1}^{n=30} m_n}$$

which allows for differences in mass flow at the various thermocouple locations. In this equation, $T_{\rm av}$ is the average outlet temperature, $T_{\rm n}$ is the temperature indication of a single one of the 30 outlet thermocouples, and $m_{\rm n}$ is the mass flow rate through the portion of the duct in which this thermocouple is located. No corrections were made for radiation or velocity effects on the thermocouple indications.

Combustor reference velocities were computed from the air mass flow rate, the combustor-inlet density, and the maximum combustor cross-sectional area (105 sq in.). The total-pressure loss was computed as the dimensionless ratio of the total-pressure loss to the combustor reference dynamic pressure. The radial distribution of temperatures at the combustor outlet was determined at each test condition investigated and at two values of combustor temperature rise (approximately 680° and 1180° F, the required values at 85 and 100 percent rated speed in the reference turbojet engine at altitudes above the tropopause). The temperature at each of the five radial positions was computed as the average of four thermocouple readings at that radial position (see fig. 2(b)). The temperature rake at each side wall of the combustor was not included in these average temperatures since the side walls exerted an influence on the flow pattern and the temperature profile which would not be obtained in a full combustor annulus.

RESULTS AND DISCUSSION

The experimental data obtained in the direct-connect duct investigation of a one-quarter segment of a $25\frac{1}{2}$ -inch annular turbojet combustor with various fuel injectors and liner configurations are presented in table II.

Accuracy and Reproducibility

Figure 10 shows values of combustion efficiency obtained with the model 13A combustor at test conditions B and C. The data from reference 1 show values of combustion efficiency obtained prior to the beginning of the investigation reported herein. Combustion efficiencies obtained in check tests with this same combustor near the conclusion of the investigation reported herein are also shown in the figure. The combustion efficiencies obtained near the conclusion of this investigation average approximately 5 percent higher than the values obtained at the beginning of the investigation.

Figure 11 compares the radial distribution of outlet temperatures obtained with the model 13A combustor in reference 1 and in the check tests with this same combustor near the conclusion of this investigation.

The combustor-outlet temperature profiles obtained in this investigation were more uneven than those obtained in reference 1. Progressive warping of the liner is believed to have caused this effect. Previous experience has shown that as the outlet temperature distribution becomes more uneven, the mass flow per unit area also becomes more uneven, with the mass flow per unit area varying inversely as the value of temperature. This means that an average combustor-outlet temperature computed from the arithmetic mean of the various thermocouple indications would be erroneously high in those cases where the temperature profile was very uneven. Consequently, the combustion efficiencies of reference 1 are believed to be reasonably accurate; whereas those obtained near the conclusion of the investigation are believed to be high because of the nonuniform outlet temperature profiles.

At a limited number of test conditions, total-pressure tubes were installed at the combustor outlet to measure the radial distribution of mass flow across the combustor outlet, and appropriate corrections were made to the thermocouple indications to allow for variations in mass flow by each thermocouple. The combustion efficiencies computed from these corrected values of outlet temperature were lower than those computed from the temperatures based on the simple arithmetic mean of the thermocouple indications. The following table shows a comparison of combustion efficiencies computed by these two methods for combustor 14I:

Test	Average outlet t	temperature, ^O F	Combustion efficiency				
condi- tion		Corrected for flow distribution		Corrected for flow distribution			
C C C	902 1140 1340 950	875 1109 1286 918	85.7 88.1 87.6 107.8	81.9 85.5 83.1 100.0			

The combustion efficiencies reported herein are values which have not been corrected for mass-flow distribution except where otherwise noted; these uncorrected combustion efficiencies cannot be considered accurate, inasmuch as they may be too high by as much as 2.0 to 8 percent at the various test conditions. The values are nevertheless significant since they show the relative performance of various combustor designs, particularly for designs investigated near the same time during the program.

Combustion Efficiency

Effect of fuel injectors. - Values of combustion efficiency obtained with the model 13 combustor and various fuel injectors at test condition C

are shown in figure 12. The curves of figure 12 were taken from the appendix, which presents more detailed efficiency data for these various combustors. Only the data of figure 12 need be considered in comparing the performance of these combustors. This comparison shows that the highest combustion efficiencies were obtained throughout most of the fuel-air ratio range with combustor 131. This combustor employed five fuel injectors, each consisting of a simple sharp-edge orifice (table I). The additional data of the appendix also show combustor 13I to be equal to, or better than, the various other combustors at the other test conditions investigated. Figure 13 shows a comparison of the combustion efficiencies obtained with the model 13I combustor with the efficiencies obtained with the model 13A combustor at test condition C. The data presented for the model 13A combustor are the data obtained near the conclusion of this investigation (fig. 10) rather than the data from reference 1. The data of figure 13 are therefore comparable for the two combustors, since they were investigated near the same time. model 13I combustor gave efficiencies 3 to 6 percent above the efficiencies obtained with model 13A. This improvement in performance was obtained by modifying the fuel injectors so that they were better adapted for handling vapor fuel.

The simple orifices of the model 13I combustor provide much less spreading of the fuel than some of the other injectors investigated. The higher efficiency of the model 13I combustor may indicate that too much spreading of the fuel is not desirable.

Effect of air-entry holes. - Combustion efficiencies obtained with the model 14I combustor are presented in figure 14. The curve for the model 13I combustor is included for comparison. The model 14I combustor gave combustion efficiencies approximately 5 percent above those of the model 13I combustor throughout the range of fuel-air ratios at test condition C. This improvement in performance is the result of revising the liner air-entry holes for better operation with vapor fuel. Since only two liner air-entry hole patterns were investigated (models 13 and 14), the optimum air-entry hole pattern was not established.

A rough indication of whether further improvements in efficiency might be obtained by additional air-entry hole modifications was obtained by operating the model 14I combustor with air injection in five of the fuel injectors. During these tests, therefore, fuel and air entered the combustor through alternate fuel injectors. The total flow rate for the air injection was 0.042 pound per second. With air injection the model 14I combustor produced efficiencies approximately 5 percent above the values obtained in model 14I combustor with no air injection. This performance of the model 14I combustor with air injection may be indicative of the performance which may be obtainable with further changes in the liner air-entry holes.

Since the model 13A combustor was developed in reference 1 to give high performance with liquid fuel, the liner was near an optimum design for liquid fuel. The data obtained with the model 14I combustor therefore indicate that the liner air-entry hole arrangement should be quite different for vapor fuel and for liquid fuel. With vapor fuel injection, a greater portion of the total air should be entered through liner perforations near the upstream end of the combustor.

Summary of effect of several design variables. - The effects of some of the more important design variables on combustion efficiency are shown in the following table, which compares efficiencies at fixed operating conditions of four different combustors:

Description of combustor	Model	Combustion efficiency at test condition C; ΔT, 680° F
Combustor developed to give high efficiency with liquid fuel	13A	54 ^a
Same combustor using vapor fuel injected through liquid-fuel injectors	13A	76.5 ^a 79.5 ^b
Fuel injectors adapted for vapor fuel	131	84.5 ^b
Liner air-entry holes adapted for vapor fuel	14I	89.5 ^b

a Data from reference 1.

Effect of liner shape. - Combustion efficiencies obtained with the model 15I combustor are presented in figure 15. The curve for the model 13I combustor is again included for comparison. The fuel injectors and the liner air-entry hole patterns were identical for these two combus-The only difference between these combustors was the shape of the combustor liner. The model 15I combustor produced a much lower pressure drop through the combustor than did the model 13I combustor, as will be subsequently discussed. Because of the design changes utilized to obtain the lower pressure drop for the model 15I combustor, the air flow through each of the air-entry holes in the upstream end of the combustor would be expected to be less than the flow through these same holes in the model 13I combustor. It might be expected, therefore, that the primary zone of the model 15I combustor would operate fuel-rich. The data of figure 15 indicate this to be the fact, since the combustion efficiencies obtained with the model 15I combustor are very much lower than the efficiencies obtained with the model 13I combustor, particularly at the

bThese values are high by about 3.5 percent.

NACA RM E53BO4

higher fuel-air ratios. The marked decrease in combustion efficiency accompanying an increase in fuel-air ratio, which is noted for the model 15I combustor, is believed typical of combustors which have a primary zone designed to operate fuel-rich.

From the foregoing considerations it would be expected that the efficiency of the model 15I combustor can be improved by additional air in the primary zone. This was accomplished by air injection through half the fuel nozzles. Two air injection rates were investigated, with the higher injection rate producing the highest efficiencies (fig. 15). With the higher rate of air injection the combustion efficiencies obtained with the model 15I combustor were only about 6 percent below those obtained with the model 13I combustor at the single high value of fuel-air ratio investigated. These results indicate that substantial improvements in combustion efficiency of the model 15I combustor may be effected by changing the design of the air-entry holes in the combustor liner.

Correlation of combustion efficiency on model 14I combustor. - The combustion efficiencies of the model 14I combustor, which gave the highest efficiencies of the various combustors investigated, are plotted in figure 16 as a function of the combustion parameter V_r/p_iT_i (ref. 3). A similar correlation curve for the model 13A combustor from reference 1 is included for comparison. The tailed symbols in figure 16 indicate data corrected for flow distribution. The curve is drawn through the corrected data points for the standard velocity conditions (test conditions A and C). As previously mentioned, the data of reference 1 are believed to be correct, so the curves for the two combustors are comparable. The correlation is presented for a single value of combustor temperature rise, 680° F, which is the value of temperature rise required for operation at 85 percent rated speed at altitudes above the tropopause. This value of required temperature rise was obtained from engine performance curves which were extrapolated to the higher altitude conditions by assuming constant efficiencies of engine components other than the combustor.

The comparison in figure 16 shows that model 14I combustor produced combustion efficiencies as much as 9 percent above those obtained with the model 13A combustor at severe operating conditions.

Estimated flight performance. - Figure 17 presents the estimated combustion efficiency (corrected values) of the model 14I combustor at various flight conditions in the reference turbojet engine; these curves were obtained by using the data of figure 16. For each value of combustion efficiency, the value of the combustion parameter was read from the curve of figure 16. The flight altitude and engine speed producing each of these values of the combustion parameter were next determined from the engine performance curves for the reference engine.

These flight altitudes and engine speeds were then plotted to give the

constant-efficiency lines of figure 17.

The curves of figure 17 are limited to the range of engine speeds from 80 to 100 percent rated speed. For this range of engine speeds the required combustor temperature rise varied from 550° to 1180° F and the combustion efficiency varied less than 3 percent for this range of combustor temperature rise. The use of figure 16, which was derived for a single value $(680^{\circ}$ F) of temperature rise, is therefore valid for this limited range of engine speed.

The two data points in figure 17 at 85 percent rated speed represent actual experimental data for the test conditions simulating flight operation at the conditions indicated on the figure. The combustion efficiencies listed beside each of these two data points match well with the values expected from interpolation between the curves of figure 17. The curves of figure 17 show that the model 14I combustor operated at efficiencies above 98 percent up to a simulated altitude of 61,000 feet at cruise (85 percent rated) engine speed.

High air flow rates. - Figure 18 shows values of combustion efficiency obtained with the model 14I combustor at air flow rates typical of current practice and 69 percent above current design practice. At these test conditions (P_i = 15 in. Hg and T_i = 268° F, simulating operation of the combustor in the reference engine at 56,000 feet and 85 percent rated speed), no detrimental effect on combustion efficiency was noted over most of the range of fuel-air ratios as a result of increasing the air flow rate.

The data of figure 18, showing no marked effect on combustion efficiency due to an increase in air flow rate (velocity) of 69 percent, are not in accord with the correlation of figure 16. For this increase in velocity of 69 percent, figure 16 indicates that a decrease in combustion efficiency of 5 percent should occur. Since this decrease did not occur, the data point for test condition E in figure 16 falls about 5 percent above the curve. This discrepancy indicates that the parameter $\rm V_r/p_iT_i$ does not properly allow for the effect of velocity on this particular combustor.

Combustor-Outlet Temperature Profiles

Figure 19 shows typical distributions of temperatures at the combustor outlet for the model 14I and 15I combustors. The radial distribution of temperatures with the model 14I combustor (fig. 19(a)) was much less uniform than the values obtained in reference 1; a curve for the model 13A combustor from reference 1 is included in figure 19(a) for comparison. The model 14I combustor employed the same secondary zone

air-entry hole pattern as did the model 13A combustor, and reference l pointed out that the outlet temperature profile was determined primarily by the arrangement of secondary air-entry holes in this combustor. The difference in temperature profiles noted for these two combustors is therefore believed to be caused primarily by the warping of the combustor liner, which occurred gradually throughout the test program reported herein.

The outlet temperature profiles obtained with model 14I combustor were not considered satisfactory, since they deviate markedly from the desired temperature distribution indicated by the dashed line in figure 19(a). The temperature distribution obtained with the model 15I combustor (fig. 19(b)) also deviates widely from the desired pattern of temperatures; no attempt was made in the investigation reported herein to remedy this temperature profile by combustor design changes.

Pressure Losses

The total-pressure drop through the combustors at test condition C for a range of density ratios (corresponding to a range of fuel-air ratios) is presented in figure 20. Since the measured pressure drop through the model 13 and model 14 combustors was the same as that reported in reference 1 for the model 13 combustor, a single curve from reference 1 is included in figure 20 to represent the pressure drop through these combustors. Experimental data are shown for the model 15I combustor. This combustor was designed for low pressure drop, and figure 20 shows that the pressure drop through the model 15I combustor was only 60 percent of the value for models 13 and 14. The pressure loss through the model 15I combustor compares favorably with the values obtained in many of the current production model combustors.

The lower pressure drop of the model 15I combustor was achieved by designing the liner so that the walls did not diverge as in previous models. This allowed a greater flow area for the air passing around the liner and entering the liner through the large secondary air-entry holes. It had been noted in appendix A of reference 1 that the high pressure drop of the previous combustor models was probably due to the flow restriction imposed on the secondary air in the flow passages outside the liner. The low pressure drop of the model 15I combustor serves to confirm this hypothesis.

SUMMARY OF RESULTS

An investigation was conducted in an annular turbojet combustor to improve combustion performance at low pressures and a high air flow rate. The design of fuel injectors, liner air openings, and liner geometries

was altered. The combustion efficiencies quoted in this section of the report have been corrected for mass flow distribution at the combustor outlet. The values quoted for simulated flight performance refer to operation of the combustor in a typical 5.2 pressure ratio turbojet engine at a flight Mach number of 0.6. The following results were obtained:

- 1. The combustor giving highest combustion efficiencies (model 141) produced efficiencies above 98 percent at altitudes up to 61,000 feet at cruise (85 percent rated) engine speed. At conditions simulating cruise at 56,000 feet, no marked effect on performance resulted from increasing the air flow rate to a value 69 percent above current design practice. However, this combustor produced an unsatisfactory radial distribution of combustor-outlet temperatures, and the pressure loss was twice as great as the value encountered with many current production model combustors.
- 2. The combustor designed to produce low pressure drop (model 15I) gave a combustor pressure loss only 60 percent as great as that obtained with the model 14I combustor. However, the combustion efficiencies of this combustor were considerably lower than those obtained with model 14I. The data indicate that the model 15I combustor requires modification to increase the amount of air entering the primary zone of the combustor in order to improve combustion efficiencies above the values reported herein.
- 3. A comparison of the combustion efficiencies obtained at operating conditions simulating cruise at 80,000 feet with different combustors shows improvements obtained as a result of changing various design features as follows:
 - (a) Increase in combustion efficiency of approximately 22 percent by changing from liquid to vapor fuel injection in a combustor (model 13A) which had been developed for liquid fuel
 - (b) Additional increase in efficiency of 5 percent by changing the fuel injectors so that they were better adapted for handling vapor fuel (model 13I)
 - (c) Additional increase in efficiency of 5 percent by changing the liner air-entry holes so that they were better adapted for vapor fuel (model 14I)

NACA RM E53B04

The over-all result of these modifications was to increase the combustion efficiency from 54 percent to 86 percent at this test condition.

APPENDIX - COMBUSTION EFFICIENCIES OF COMBUSTOR MODELS 13 AND 14

WITH VARIOUS FUEL INJECTORS

The combustion efficiencies obtained with the model 13 and model 14 combustors with various fuel injectors are presented in figures 21 and 22, respectively. The curves from figure 21 for test condition C were compared in figure 12 where model 13I was shown to provide the highest efficiencies over most of the fuel-air ratio range. Comparing the efficiencies of these combustors at other test conditions leads to the same conclusion: namely, combustor model 13I is equal to or better than the various other combustors of figure 21.

It was shown with combustor model 13 (figs. 21(e) and 21(f)) that combustion efficiency increased as the fuel injector orifice diameter was increased for the three orifice sizes investigated. It therefore appeared possible that a further increase in fuel orifice size might result in further gains in efficiency. This possibility was investigated by using larger orifices in the model 14 combustor (model 14K). The results are shown in figure 22, where the efficiencies of the model 14K combustor are compared with those of model 14I. parison indicates that a further increase in fuel orifice size was not beneficial.
